Abstract

Herein we report on the hydrothermal synthesis of niobium pentoxide on carbide-derived carbon (Nb\textsubscript{2}O\textsubscript{5}/CDC) with a layered structure. The presence of phenylphosphonic acid guides the deposition during preparation, leading to the formation of amorphous Nb\textsubscript{2}O\textsubscript{5} particles which are 4–10 nm in diameter and homogeneously distributed on the CDC framework. Electrochemical testing of the Nb\textsubscript{2}O\textsubscript{5}/CDC electrode indicated that the highest capacitance and Coulombic efficiency occurred using an electrolyte comprised of 1 M lithium perchlorate in ethylene carbonate/dimethyl carbonate. Subsequent heat treatment of Nb\textsubscript{2}O\textsubscript{5}/CDC in CO\textsubscript{2} environment led to crystallization of the Nb\textsubscript{2}O\textsubscript{5}, allowing reversible Li\textsuperscript{+} intercalation/de-intercalation. For sweep rates corresponding to charging and discharging in under 3 min, a volumetric charge of 180 C cm\textsuperscript{-3} and Coulombic efficiency of 99.2\% were attained.

1. Introduction

Electrochemical capacitors (ECs), also called supercapacitors, are energy storage devices that can be rapidly charged/discharged and repeatedly cycled without significant capacitance decay [1]. ECs have been successfully commercialized and implemented in consumer electronics, transportation, back-up power systems, etc. [2,3]. Based on distinct charge storage mechanisms, ECs can be
categorized into two primary types. Traditional electrical double layer capacitors (EDLCs), which store charge by electrostatic adsorption of electrolyte ions on the electrode-electrolyte interface, typically rely on porous carbon electrodes with high specific surface areas [4]. The other type of ECs, pseudocapacitors, employ fast and reversible surface or near-surface redox reactions of electroactive species for charge storage [5].

Carbon materials are commonly used in EDLCs due to their low cost, high mechanical stability, good electrical conductivity, and high surface area [6,7]. While the ideal attainable capacitances reach 250 F g⁻¹ for carbon materials with specific surface areas (SSA) of >2000 m² g⁻¹, the practical values are usually around 150 F g⁻¹ due to the complexity of the pore structure, which limits the accessibility of electrolyte ions and restricts the surface area utilization [5]. One of the most promising approaches to greatly improve the limited specific capacitance (Cₑ) of carbon materials is by addition of redox-active (pseudocapacitive) species. For instance, nitrogen doping [8], and the deposition of transition metal oxides (TMOs) [9,10] or conducting polymers [11] onto the carbon framework has been shown to increase energy storage density significantly in various electrolytes.

Niobium pentoxide (Nb₂O₅) is considered to be one of the most promising transition metal oxides (mTOs) for pseudocapacitive energy storage. It has been widely studied in lithium-ion batteries (LIB) [12], electrochemical hydrogenation catalysts [13], gas sensing [14], electrochromic devices [15] and solar cells [16]. Since its lithium intercalation potential closely matches the lowest unoccupied molecular orbitals (LUMO) of the organic liquid-carbonate electrolyte [17], Nb₂O₅ is a safe anode with a high theoretical capacity of 200 mAh g⁻¹ for LIBs. Nb₂O₅ exhibits a variety of crystalline allotropes, with orthorhombic (T-Nb₂O₅), pseudo-hexagonal (TT-Nb₂O₅), tetragonal (M-Nb₂O₅) and monoclinic (H-Nb₂O₅) [18,19] structures being the most common ones. The T-Nb₂O₅ phase is reported to be one of the most attractive pseudocapacitive materials due to its surface reaction and Li⁺ intercalation. Dunn et al. showed fast lithium intercalation kinetics for T-Nb₂O₅, which was accompanied by little or no structural change [20]. The high intercalation pseudocapacitance of T-Nb₂O₅ could have several sources [21–23]. For example, Simon et al. found that the large pseudocapacitance is a consequence of the fast Li⁺ intercalation capability within the (001) planes of the T-Nb₂O₅ [21], while Ganesh et al. concluded that the origin of high-rate intercalation pseudocapacitance is due to the unique open channels of NbO₆ sheets that reduce the energy barrier and facilitate the local charge transfer between lithium and oxygen-containing structures [23].

Although Nb₂O₅ displays high levels of pseudocapacitance, its low electronic conductivity (≈10⁻⁶ S cm⁻¹) [12] limits its performance. Moreover, it is important to note that all previously reported studies with this material relied on electrode thicknesses below 40 μm [21]. Undoubtedly, if the thickness is increased, volumetric capacitance would increase while power density would suffer. Therefore, increasing the conductivity and thickness of the electrodes while retaining their excellent energy density and power handling properties is critical. Previous efforts to address this problem include deposition of a carbon layer on the Nb₂O₅ nano-crystals to fabricate Nb₂O₅–C core–shell composites [24] and mixing of pseudo-hexagonal Nb₂O₅ powders with carbon nanotubes (CNTs) to form a Nb₂O₅/CNT composite [25]. In the latter case, the incorporated CNTs not only increased the conductivity of the electrode, but also provided additional capacitive storage [25]. However, only a few reports are available regarding the growth of Nb₂O₅ on carbon [26,27], and we are unaware of any results in which a highly crystallized T-Nb₂O₅ deposited on a carbon matrix was considered for pseudocapacitor application.

The work presented here represents the first report in which Nb₂O₅ nanoparticles were hydrothermally deposited onto a conductive carbide-derived carbon (Nb₂O₅/CDC) with a layered structure. The effects of phenylphosphonic acid addition during synthesis and the influence of electrolyte composition on the resulting electrochemical performance were studied systematically. A CO₂ oxidation treatment was developed which enabled us to obtain the desired T-Nb₂O₅ phase for improved capacitance. This study describes a new route for the synthesis of Nb₂O₅/carbon composites for pseudocapacitor electrodes in energy storage devices.

2. Materials and experimental

2.1. Preparation of CDC

Titanium aluminum carbide (Ti₂AlC) powder was chosen as the carbon precursor because it produces mesoporous CDC with a graphene-like layered structure. Details of the chlorination procedure were described previously [28]. The Ti₂AlC powder (Kanthal, Sweden) was placed in the middle of a horizontal quartz tube, followed by Ar purge for 1 h at room temperature. Under continuous Ar flow, the temperature was raised to 800 °C at a rate of 30 °C min⁻¹ and held for 1 h. The gas was then switched to Cl₂, leading to complete etching by heating for 3 h at 800 °C at a flow rate of 10 scm, followed by H₂ treatment at 600 °C for 2 h. The furnace was cooled to room temperature under Ar flow. The resulting carbide-derived carbon is subsequently referred to as CDC.

2.2. Preparation of Nb₂O₅/CDC

100 mg of CDC were sonicated in a 20 mL aqueous solution of 0.30 M ammonium niobate oxalate hydrate C₄H₄Na₂NbO₉·xH₂O (99.99%, Sigma–Aldrich) and 0.33 M phenylphosphonic acid C₆H₅PO₃ (PPA, 98%, Sigma–Aldrich) for 30 min. 400 mg of urea (CO(NH₂)₂, Sigma Aldrich) powder was added, and the mixed solution was subsequently transferred to a 40 mL Parr bomb for hydrothermal treatment at 200 °C for 96 h. The product was rinsed with DI water and centrifuged several times until pH of the solution reached 7. Finally, the material, referred to as Nb₂O₅/CDC, was collected and dried at 100 °C for 24 h. For comparison, Nb₂O₅/CDC without PPA was also prepared.

2.3. Preparation of Nb₂O₅/CDC-CO₂

200 mg of Nb₂O₅/CDC powders were loaded into a horizontal quartz tube furnace. After purging with Ar for 60 min, the furnace was heated under continuous Ar flow to 850 °C at a rate of 10 °C min⁻¹ and held for 30 min. The Ar gas was switched to CO₂ and kept for 1 h at 850 °C at a flow rate of 10 scm. The sample (referred to as Nb₂O₅/CDC-CO₂) was then cooled to room temperature in Ar. For comparison, CDC was treated using a similar method and is denoted as CDC-CO₂.

2.4. Materials characterization

The morphology of the materials was studied using scanning electron microscopy (SEM, Zeiss Supra 50VP, Germany) and transmission electron microscopy (TEM, JEM 2100, Japan). Specific surface area (SSA) and pore size distributions were evaluated by nitrogen sorption measurements at 77 K using a Quadrasorb gas sorption instrument (Quantachrome, USA). Samples were degassed at 120 °C for 24 h prior to the measurement. The specific surface area was calculated using the Brunauer–Emmett–Teller (BET)
method at the relative pressure \( (P/P_0) \) range of 0.05–0.2. The total pore volume \( (V_1) \) was calculated at \( P/P_0 = 0.99 \) while the pore size distribution was derived from quench-solid density functional theory (QSDFT) with an assumed slit-shaped pore geometry. The phases of the materials were studied via X-ray diffraction (XRD, Siemens D500, Germany). The carbon content of the \( \text{Nb}_2\text{O}_5/\text{CDC} \) material was determined using thermogravimetric analysis (TGA, TA Instruments, USA) via oxidation in air environment. During the measurement, samples were initially held at 100 °C for 1 h to remove any trapped water and subsequently heated to 800 °C at 2.5 °C min \(^{-1} \).

2.5. Electrochemical characterization

2.5.1. Nanocrystalline electrode preparation

For initial electrochemical characterization, a nanocrystalline electrode, similar to what we have reported previously \cite{18,20}, was used. This approach maximizes the contact of every particle of the active material to the current collector, with ample electrolyte available to provide ionic conduction. No additional carbon or binder is needed as these electrodes were developed with the intent of directly characterizing the active material of interest. Furthermore, only a small amount of active material is required. To make each electrode, 1 mg of active material is combined with 1 mL of ethanol and sonicated to form a dilute suspension of particles. 10 \( \mu \)L of this suspension is drop cast onto a 1 cm\(^2 \) section of stainless steel which has been cleaned by an O2 plasma etch immediately prior to drop casting. The region outside the 1 cm\(^2 \) deposition area is masked with Mylar tape to avoid its contribution to the capacitive energy storage measurement. Each electrode is dried overnight at 120 °C under vacuum before being transferred into an Ar-filled glove box. The electrochemical properties of these nanocrystalline electrodes were characterized in a threeneck flooded cell using lithium foil as counter and reference electrodes.

2.5.2. Composite electrode preparation

A second type of electrode, which we term a composite electrode, was also prepared. This electrode is based on combining the electrochemically active material (the \( \text{Nb}_2\text{O}_5/\text{CDC} \) with a carbon conductive agent (carbon black, 99.9%, Alfa Aesar) and a binder (polytetrafluoroethylene, or PTFE, 60 wt.%, Sigma–Aldrich). The materials were mixed in a mass ratio of 8:1:1 in ethanol (99.9%, Fisherbrand). After evaporation of ethanol, the paste was rolled into a flat film, formed into electrode and vacuum dried for 24 h. Each working electrode was 1.5 mg in weight, 5 mm in diameter and 70 \( \mu \)m in thickness. Electrodes were also fabricated from YP-50F activated carbon (Kuraray, Japan, SSA of 1470 m\(^2 \) g\(^{-1} \)) and 0.85 nm pore diameter). These electrodes were prepared without adding carbon black. The mass ratio of YP-50F to PTFE was 95:5. Each YP-50F electrode was 15 mg.

2.5.3. Electrolyte studies

Four types of electrolytes were prepared: 1 M lithium perchlorate in ethylene carbonate/dimethyl carbonate (1 M \( \text{LiClO}_4/\text{EC/DME} \), 1 M \( \text{LiClO}_4 \) in acetonitrile (1 M \( \text{LiClO}_4/\text{AN} \), 1 M lithium hexafluorophosphate in ethylene carbonate/diethyl carbonate (1 M \( \text{LiPF}_6/\text{EC/DEC} \) and 1 M lithium perchlorate + 1 M tetraethyl ammonium tetrafluoroborate (TEABF\(_4 \)) in ethylene carbonate/ diethyl carbonate (\( \text{LiClO}_4 \); TEABF\(_4 \)/EC/DME). The mixed solvents, EC/DME and EC/DEC, used a 1:1 volume ratio.

2.5.4. Electrochemical characterization of composite electrodes

The electrochemical measurements of the \( \text{Nb}_2\text{O}_5/\text{CDC} \) composite electrodes were carried out using a three-electrode configuration in Swagelok cells. The \( \text{Nb}_2\text{O}_5/\text{CDC} \) composite served as the working electrode, an overcapacitive YP-50F electrode was the counter and Ag/AgCl was the reference electrode. Cyclic voltammetry (CV) at various sweep rates and galvanostatic charge–discharge (GCD) at different current densities were performed using a VMP3 potentiostat (Bio-Logic Inc., France). All the cells were cycled initially for 20 times at 20 mV s\(^{-1} \). The stored charge was derived from the 20th cycle of cathodic CV using the following equation:

\[
C_i = \int_{1}^{2} \frac{1}{mv} dV
\]

while the Coulombic efficiency was derived based on the following equation:

\[
\eta = \frac{C_{\text{cathodic}}}{C_{\text{anodic}}}
\]

\[
C_i = C_j \times \rho
\]

where, \( C_i \) (C g\(^{-1} \)) and \( C_j \) (C cm\(^{-3} \)) are, respectively, the gravimetric charge and volumetric charge of the working electrode. \( i \) is the current response (mA), \( v_1 \) and \( v_2 \) represent, respectively, the initial and final potentials \( (V_i, v) \) is the scan rate (mV s\(^{-1} \)), and \( m \) is the active mass (g) in one electrode. In Eqn. \( (2) \), \( \eta \) is the coulombic efficiency, \( C_{\text{cathodic}} \) is the cathodic charge while \( C_{\text{anodic}} \) is the anodic charge, \( \rho \) (g cm\(^{-3} \)) is the bulk density of the electrode. All the reported electrochemical results were averaged from three parallel experiments.

3. Results and discussion

3.1. Materials synthesis

Fig. 1 shows a schematic for the preparation of \( \text{Nb}_2\text{O}_5/\text{CDC} \) materials. The layered CDC synthesized at 800 °C was chosen due to the presence of mesopores in the material and an adequate specific surface area (\( \sim 800 \text{ m}^2 \text{ g}^{-1} \)) \cite{28}, which is suitable for \( \text{Nb}_2\text{O}_5 \) deposition. After \( \text{Nb}_2\text{O}_5 \) was deposited hydrothermally onto/between the layers of the CDC, the material’s microstructure resembled large bricks with severe aggregation (Fig. 1, top circle). This can be explained by the i) hydrophobicity of the CDC surface and ii) high surface energy of \( \text{Nb}_2\text{O}_5 \) leading to the growth of larger agglomerates. In contrast, addition of the PPA into the synthesis suspension led to the homogeneous distribution of \( \text{Nb}_2\text{O}_5 \) particles on the CDC surface with a much smaller particle size, suggesting that PPA guides the uniform deposition of \( \text{Nb}_2\text{O}_5 \) nanoparticles. The likely explanation for this effect is that PPA modified the surface chemistry of CDC and, at least partially, terminated carbon with phosphonic acidic groups thus providing numerous nucleation sites (see lower illustrations of Fig. 1). As a result of the different composite morphologies, the electrochemical behavior of these composites is different, as discussed later.

3.2. Composite morphology and structure

The SEM image in Fig. 2a and TEM image in Fig. 2c indicate CDC has a layered morphology, which is derived from the layered Ti2AlC precursor through a one-step chlorination process. After the hydrothermal treatment, the CDC surface becomes rougher (Fig. 2b) and is decorated with uniformly distributed \( \text{Nb}_2\text{O}_5 \) particles (Fig. 2d). The TEM image in Fig. 2e shows that the \( \text{Nb}_2\text{O}_5 \) nanoparticles have sizes ranging from 4 nm to 10 nm. Fig. 3 shows SEM images of \( \text{Nb}_2\text{O}_5/\text{CDC} \) after CO\(_2 \) oxidation. The layered structure of the composite material was maintained after heat treatment under CO\(_2 \) (Fig. 3a), demonstrating that the mild oxidation process does
not affect the overall structure of the Nb$_2$O$_5$/CDC. However, as revealed by higher magnification SEM images (Fig. 3b), the Nb$_2$O$_5$ nanoparticles become more visible on the CDC layers, suggesting possible aggregation and growth of the oxide particles and also partial oxidation and removal of CDC substrate.

XRD was used to analyze the structure of the CDC and the as-prepared composite as shown in Fig. 4. The broad [002] peak
centered at \(2\theta = 25^\circ\) signifies that CDC is amorphous to X-rays. After hydrothermally depositing \(\text{Nb}_2\text{O}_5\), the XRD pattern of the composite looks similar to CDC, suggesting that the 4–10 nm \(\text{Nb}_2\text{O}_5\) nanoparticles are also X-ray amorphous. Because crystalline phases of \(\text{Nb}_2\text{O}_5\) are beneficial for capacitive energy storage \([20,22]\), heating the \(\text{Nb}_2\text{O}_5/\text{CDC}\) composite is required for activating the pseudocapacitance.

Previous studies show that the \(T\)-\(\text{Nb}_2\text{O}_5\) phase can be produced by heat treatment of amorphous \(\text{Nb}_2\text{O}_5\) at temperatures higher than 600 °C in air or oxygen. However, oxygen-excessive environments are not suitable for the heat treatment of CDC/\(\text{Nb}_2\text{O}_5\) hybrid materials as it results in the combustion of carbon. On the other hand, heat treatment in an oxygen-free environment (e.g., \(\text{N}_2\) or \(\text{Ar}\) flow) will likely promote the formation of \(TT\)-\(\text{Nb}_2\text{O}_5\). A comparison of structure of the \(T\)- and \(TT\)-\(\text{Nb}_2\text{O}_5\) shows that the hexagonal unit cell of the latter phase contains only half of the formula equivalent (\(\text{NbO}_2.5\)), with one oxygen vacancy per unit cell \([29]\). Therefore, to achieve the desired \(T\)-\(\text{Nb}_2\text{O}_5\) phase, it is preferable to carry out the heat treatment in an oxygen-containing environment. Accordingly, heat treatments were performed under \(\text{CO}_2\) flow to provide a source of oxygen to reach the required ratio of \(\text{Nb}:\text{O} = 2:5\) and thus produce the desired crystalline phase. Being a milder oxidant in comparison to \(\text{O}_2\) or air, \(\text{CO}_2\) was not expected to lead to the complete oxidation of carbon. Our heat treatment studies confirmed this assumption.

As seen from XRD data (Fig. 4a), \(\text{CO}_2\) treatment of CDC had no significant effect on the graphitic structure of carbon, whereas sharp peaks centered at 22.6°, 28.4°, 36.5°, 42.8°, 44.2°, 46.1°, 50.1°, 55.2° and 58.5° appeared in the XRD pattern of \(\text{Nb}_2\text{O}_5/\text{CDC}\) samples after \(\text{CO}_2\) annealing for 1 h at 850 °C. These peaks can be indexed as (001), (180), (181), (2100), (2110), (002), (380), (202), (2160) reflections of orthorhombic (\(T\)-phase) \(\text{Nb}_2\text{O}_5\) (JCPDS no. 30-0873) \([22]\). Moreover, peaks centered at 28.8°, 42.8° and 44.2° in \(\text{Nb}_2\text{O}_5/\text{CDC}-\text{CO}_2\) clearly distinguish the \(T\)-phase \(\text{Nb}_2\text{O}_5\) from other phases.

![Fig. 3. SEM images of \(\text{Nb}_2\text{O}_5/\text{CDC}-\text{CO}_2\) at lower (a) and higher (b) magnification.](image)

![Fig. 4. Textural and porosity studies of the CDC substrate and the \(\text{Nb}_2\text{O}_5/\text{CDC}\) composite with/without \(\text{CO}_2\) heat treatment: (a) XRD patterns for the various electrochemical materials: the initial CDC after chlorination, the CDC after heat in \(\text{CO}_2\) (\(\text{CDC}-\text{CO}_2\)), after hydrothermal deposition of \(\text{Nb}_2\text{O}_5\) (\(\text{Nb}_2\text{O}_5/\text{CDC}\)) and heat treatment in \(\text{CO}_2\) (\(\text{Nb}_2\text{O}_5/\text{CDC}-\text{CO}_2\)); (b) XRD patterns showing the effect of annealing environment on the \(\text{Nb}_2\text{O}_5\) phase composition; (c) \(\text{N}_2\) sorption isotherms and (d) pore size distributions (d) of CDC and \(\text{Nb}_2\text{O}_5/\text{CDC}\) calculated using the QSDFT model. Inset shows the PSD of \(\text{Nb}_2\text{O}_5/\text{CDC}\).](image)
In addition to the peaks corresponding to 7-Nb2O5, some lower intensity peaks were identified suggesting the presence of a small amount of the monoclinic Nb2O5 after the CO2 treatment. For comparison, the XRD pattern of Nb2O5/CDC treated in Ar at the same temperature and duration is shown in Fig. 4b. Close examination reveals that peaks centered at 22.6°, 28.5°, 36.7°, 46.2°, 50.6°, 55.3°, 59.1°, 64.9°, 70.8°, correspond to (001), (100), (101), (002), (110), (102), (200), (201), (112) reflections of pseudo-hexagonal Nb2O5 (77-phase, JCPDS no. 28-0317), respectively. Thus, the treatment under CO2 flow promotes the formation of the desired orthorhombic phase of Nb2O5.

The surface area and pore size distribution (PSD) of CDC and its composites were analyzed using N2 sorption, as shown in Fig. 4c–d. The type-IV isotherms suggest mesoporous structures for both materials. The PSD in Fig. 4d reveals substantial volumes of micropores and mesopores in CDC, with a BET specific surface area (SSA) of 538 m² g⁻¹ and a pore volume of 0.506 cc g⁻¹, as shown in Table 1. Nb2O5 formation and pore blocking in CDC by Nb2O5 led to a decrease in SSA to less than 150 m² g⁻¹. The PSD of Nb2O5/CDC is similar to CDC (inset of Fig. 4d) with the presence of mesopores, which are beneficial for electrolyte transport within the electrode. Table 1 shows the porosity parameters of the CO2 oxidized samples, revealing that CO2 oxidation slightly increases the BET-SSA and pore volume in both samples. The combination of results shown in Fig. 4 and Table 1 indicates that CO2 treatment has relatively little effect on morphology and graphitic content of CDC, but leads to crystallization of Nb2O5.

To determine the fraction of pseudocapacitive Nb2O5 in the composites, TGA was carried out in air (Fig. 5). Both Nb2O5/CDC and Nb2O5/CDC-CO2 have similar combustion onset temperatures (~400 °C) and temperatures of the maximum combustion rate (~550 °C) (Fig. 5b). The residual mass can be attributed to the remaining Nb2O5 in each composite, since the CDC exhibited a residue of <1 wt.%(data not shown). The as-synthesized Nb2O5/CDC sample has a loading of 26 wt.% Nb2O5. This fraction increases to 45 wt.% because of partial oxidation of carbon during the annealing in CO2. It should also be noted that the CO2 thermal treatment could activate the CDC and lead to a higher electric double layer contribution to the total capacitance [31].

### 3.3. Electrochemical properties

#### 3.3.1. The effect of PPA addition for nanocrystalline electrodes

As previously discussed, the addition of PPA into the hydrothermal synthesis guides the uniform deposition of Nb2O5, which is expected to exhibit improved electrochemical performance compared to the composite prepared without addition of PPA. We used nanocrystalline electrodes to quickly determine how the electrochemical properties changed for the different synthesis strategies. The nanocrystalline electrodes are useful for this application as each electrode only requires ~10 μg of active material, allowing for the fast and efficient screening of materials, similar to microelectrodes used in our previous studies [32]. As shown in Fig. 6, Nb2O5/CDC without PPA exhibits a CV response with no evidence of Nb2O5 redox peaks. Moreover, the calculated specific capacitance is lower than CDC at all sweep rates, which could be attributed to the much lower SSA and poor utilization of the pseudocapacitive properties of Nb2O5 due to its aggregation. However, with the addition of PPA into the suspension, the composite shows a well-defined anodic peak at 1.5 V vs. Li/Li+ and provides a much higher specific capacitance at all sweep rates, further verifying the PPA’s positive effect on promoting utilization of Nb2O5. For convenience, all of the composites discussed in the following sections were prepared with the PPA addition. It should also be noted that for Nb2O5/CDC with PPA (Fig. 6a), the sharp peak on the cathodic sweep was due to lithiation of amorphous Nb2O5 and irreversible electrochemical reactions leading to electrolyte decomposition, as the Coulombic efficiency was only 95%.

#### 3.3.2. Electrolyte studies

The experiments directed at the effect of Li⁺ containing electrolyte systems were carried out on the Nb2O5/CDC composite electrodes (Fig. 7). The broad cathodic peak observed in the anodic sweep in all electrolyte systems (Fig. 7a) indicated the delithiation of amorphous Nb2O5. It was found that 1 M LiClO4/EC/DMC provided a high Coulombic efficiency (96–99%) even at relatively low scan rates (Fig. 7c) without compromising specific capacitance values (Fig. 7b). This electrolyte system was therefore selected for use in the more detailed electrochemical studies.

3.3.3. Effect of Nb2O5 phase content

The results shown in Fig. 8 summarize how the capacitive storage properties of the composite electrodes are influenced by the presence of Nb2O5 and the CO2 treatment. For the CDC, a typical rectangular CV shape is observed throughout the entire potential range (−1.8 to 0 V vs. Ag/AgCl) indicating pure capacitive behavior during the charge/discharge process arising from electric double layer capacitance. At 10 mV s\(^{-1}\), CDC provided −100 C g\(^{-1}\). This value is less than the result (140 C g\(^{-1}\)) for nanocrystalline electrodes of CDC (Fig. 6), however, the loading for the CDC electrodes in Fig. 8, 7.6 mg cm\(^{-2}\), is more than 50 times greater than that of the nanocrystalline CDC electrodes. The capacitance of the CDC at sweep rates greater than 10 mV s\(^{-1}\) is relatively unaffected by the CO2 heat treatment (Fig. 8b). This result shows that CO2 oxidation of CDC under the same conditions as Nb2O5/CDC-CO2 did not have much effect on its electrochemical performance. The deposit of amorphous Nb2O5 onto CDC (i.e., Nb2O5/CDC) increased the specific capacitance over the entire range of sweep rates. Such an increase originates from the additional pseudocapacitive contribution of the Nb2O5, as seen from the broad redox peaks between −1.8 V and −0.8 V (vs. Ag/AgCl).

As shown in Fig. 4a, CO2 treatment leads to crystallization of the amorphous Nb2O5 and the formation of orthorhombic and monoclinic phases. The oxidized Nb2O5 features two pairs of redox peaks at −1.55/−1.35 V and −1.32/−1.12 V (vs. Ag/AgCl). Moreover, the composite sample is characterized by i) good rate handling capability (Fig. 8b), ii) well-defined cathodic and anodic peaks at various scan rates (Fig. 8c), iii) a higher Coulombic efficiency compared to amorphous Nb2O5 (Fig. 8d) and iv) highly reversible lithiation/delithiation processes. As a result, Nb2O5/CDC-CO2 shows the
highest stored charge $-220 \text{ C g}^{-1}$ at 1 mV s$^{-1}$, which decreases to $157 \text{ C g}^{-1}$ at 10 mV s$^{-1}$, as shown in Fig. 8b. The relative amount of capacitance decay with increasing sweep rates is comparable to that of the CDC component, suggesting that the carbon architecture is not optimized. Fig. 9a presents the GCD profiles of Nb$_2$O$_5$/CDC-CO$_2$. The deviation from the linear profile below $-1.2 \text{ V}$ is consistent with the mechanism regarding the additional charge storage contribution. Moreover, the small IR drop at 2 A g$^{-1}$ indicates the good power handling properties of the Nb$_2$O$_5$/CDC. The increase in capacitance can also be inferred from the GCD profile in Fig. 9b, as prolonged charge–discharge time was found in Nb$_2$O$_5$/CDC-CO$_2$ at 1 A g$^{-1}$.

The present paper provides insight regarding the capacitive energy storage properties one can expect upon adding a pseudo-capacitive component to a carbon-based support. As mentioned previously, the former stores charge by a redox reaction while the latter involved electrical double layer processes. Here again we characterize the charge storage in terms of C g$^{-1}$ to analyze the respective contributions. For Nb$_2$O$_5$, the theoretical value for forming Li$_2$Nb$_2$O$_5$ from Nb$_2$O$_5$ is $728 \text{ C g}^{-1}$. The effect of adding Nb$_2$O$_5$ to CDC for increased energy storage is shown in Table 2. Again, we have used the data taken at 10 mV s$^{-1}$ since 3 min of discharging and charging represents a reasonable time frame for energy storage based on capacitive processes for both electrical

double layer and pseudocapacitance. The results show that by adding Nb2O5, the stored charge increases, demonstrating the pseudocapacitive contribution from the Nb2O5 redox sites. However, the energy storage properties for the Nb2O5/CDC and Nb2O5/CDC-CO2 composites are only 40%–50% of their computed values based on the compositions used in the study. We attribute this behavior to there being much less pseudocapacitive contribution from the Nb2O5 phase. In fact, if we assume that the CDC contributes the same relative amount of charge storage based on control experiments (see Table 2), then Nb2O5 provides only about 60 C g⁻¹ for amorphous Nb2O5 and 100 C g⁻¹ for crystalline Nb2O5. These values are far below what is expected for the pseudocapacitive contribution from Nb2O5. The reason for this less than expected pseudocapacitive response is likely to be a combination of factors including poor electrical contact between the carbon and Nb2O5 and occluding the Nb2O5 surfaces so that electrolyte is not accessible to the redox-active material. Electrolyte access may be the key here as a more porous composite that used carbon nanotubes with Nb2O5 (pseudo-hexagonal) exhibited greater gravimetric charge storage (–400 C g⁻¹) although with lower volumetric charge storage [23].

Another consideration with the Nb2O5/CDC composites is their power handling properties. It is not surprising that the high-rate performance of the Nb2O5/CDC-CO2 electrodes is less impressive than our earlier work with nanocrystalline electrodes [20] as the electrodes used in the current study were 70 µm thick and contained insulating PTFE binder. The density of the Nb2O5/CDC-CO2 electrode, however, was 1.1 g cm⁻³, a significantly greater value. Thus, the highest volumetric charge reaches 242 C cm⁻³ at 1 mVs⁻¹. Moreover, the volumetric capacitance for the Nb2O5/CDC-CO2 electrode exceeds 180 C cm⁻³ (100 F cm⁻²) at sweep rates corresponding to the 3 min charge and discharge conditions mentioned above. These values are higher than, for example, three-dimensional MnO2/carbon nanofibers (90 F cm⁻²) on the same charge–discharge time range [33]. It should also be noted that the Coulombic efficiency reached values as high as 99.2% at 10 mVs⁻¹. Future efforts will focus on further optimization of conductivity of the Nb2O5/CDC, while increasing the loading of 7-Nb2O5, leading to higher gravimetric and volumetric capacitances in combination with good power handling.

4. Conclusions

Nb2O5/CDC composites with a layered structure were prepared by the hydrothermal deposition of Nb2O5 on the surface of CDC. Amorphous Nb2O5 nanoparticles on the order of 4–10 nm were homogeneously distributed on the CDC surface when phenylphosphonic acid was added. High-temperature treatment in CO2 was found to be effective in converting the amorphous Nb2O5 into orthorhombic and monoclinic phases without degrading the CDC support. This treatment resulted in improved electrochemical characteristics such as reversible Li⁺ intercalation/de-intercalation, increased gravimetric capacitance (157 C g⁻¹), higher volumetric capacitance (180 C cm⁻³) and Coulombic efficiency of 99.2% at a charge–discharge time of 3 min. Thus, annealing in CO2 offers a simple and environmentally benign method of obtaining crystalline niobium pentoxide with increased energy storage properties.

Acknowledgments

The work reported in this paper was performed at Drexel University and the University of California, Los Angeles. The authors greatly appreciate the support of the research from the U.S. Department of Energy, Office of Electricity Delivery and Energy Reliability, Energy Storage Systems Program, through Sandia National Laboratories. C. Zhang was supported by the Chinese Scholarship Council (CSC) (grant no. 201206740035). B. Dyatkin was supported by NSF grant CNS-0960061. K. Jost is acknowledged for the schematic drawing. O. Mashtalir assisted with the TEM analysis. Electron microscopy studies were carried out at the Drexel Centralized Research Facilities (CRF).
