On-Chip MXene Microsupercapacitors for AC-Line Filtering Applications

Qiu Jiang, Narendra Kurra, Kathleen Maleski, Yongjiu Lei, Hanfeng Liang, Yizhou Zhang, Yury Gogotsi,* and Husam N. Alshareef* 

Microsupercapacitors (MSCs) with high energy densities offer viable miniaturized alternatives to bulky electrolytic capacitors if the former can respond at the kilo Hertz (kHz) or higher frequencies. Moreover, MSCs fabricated on a chip can be integrated into thin-film electronics in a compatible manner, serving the function of ripple filtering units or harvesters of energy from high-frequency sources. In this work, wafer-scale fabrication is demonstrated of MXene microsupercapacitors with controlled flake sizes and engineered device designs to achieve excellent frequency filtering performance. Specifically, the devices (100 nm thick electrodes and 10 µm interspace) deliver high volumetric capacitance (30 F cm⁻³ at 120 Hz), high rate capability (300 V s⁻¹), and a very short relaxation time constant (τ₀ = 0.45 ms), surpassing conventional electrolytic capacitors (τ₀ = 0.8 ms). As a result, the devices are capable of filtering 120 Hz ripples produced by AC line power at a frequency of 60 Hz. This study opens new avenues for exploring miniaturized MXene MSCs as replacements for bulky electrolytic capacitors.

1. Introduction

Aluminum electrolytic capacitors (AECs) are widely used for delivering pulse power and filtering/smoothing 120 Hz alternating current (AC) signals, which are produced by rectifying AC-line power of 60 Hz (the line power frequency used in the United States). However, AECs are bulky with low volumetric energy density; thus it is essential to develop miniaturized energy storage units that can replace AECs for both pulse power and AC-line filtering applications.[1-5] For instance, line-powered circuits require stable direct current (DC) voltage for reliable operation, while emerging technologies, such as the internet of things (IoT), wireless sensor networks, biosensors, medical implants, and wearable electronics, require compatible micro-power modules that can harvest and store pulse power for the design of “autonomous on-chip technology”.[6-8] However, AECs suffer from bulky size due to their low volumetric energy density.

Pioneering work by Miller in 2010 demonstrated efficient AC-line filtering using graphene-based electrochemical capacitors (ECs) in a stacked configuration, a result which established high energy density electrical double layer capacitors as promising devices for AC-line filters.[3] The key parameters in the design of AC-line filters based on ECs include: i) Good ohmic contact of electrode materials with current collectors to reduce the interfacial impedance between the two; ii) high external surface area with large sized pores (should not be microporous) to minimize electrolyte resistance; iii) good electronic/ionic conductivity of electrode materials, especially layered materials without interparticle resistance.

Microsupercapacitors (MSCs) are evolving on-chip energy storage devices that can offer compatible integration with thin film electronics with a much higher power density and cycle life over microbatteries.[3,6,9-11] Interdigitated electrode architectures can potentially achieve more efficient ionic transport, which is a key advantage over the sandwich (parallel electrode) configuration,[12] especially in the case of 2D materials with flakes stacked parallel to the current collector. The sandwich design hinders ionic transport due to the presence of separator and larger distance between electrodes and offers inferior performance compared to in-plane interdigital design. Upon shortening the ion transportation pathways, we expect that the planar microsupercapacitor configuration can achieve good frequency response and be suitable for AC-line filtering applications. Furthermore, on-chip microsupercapacitors can offer as much as 50% gain in volumetric capacity over the sandwich configuration.[9]

MSCs fabricated using carbonaceous materials such as carbide-derived carbon (CDC),[13] onion-like carbon (OLC),[14] laser scribed graphene (LSG),[15] and other materials[16-19] have been demonstrated with high rate capabilities. Even though significant advances have taken place recently in terms of...
fabrication and material processing, the operational speeds of most of MSCs have not reached the level required for AC-line filtering applications. Lin et al., developed 3D micro-supercapacitors based on graphene and carbon nanotube carpet for AC-line filtering applications, showing a volumetric capacitance of 2 F cm\(^{-3}\) and relaxation time constant of 0.83 ms. Their study demonstrated that high temperature growth of carbon materials with open structures is an effective strategy to fabricate supercapacitors suitable for AC-line filtering.

However, it has been challenging to develop AC-line filtering function using solution processable pseudocapacitive materials, which typically suffer from limited electronic conductivity and hence poor charge transfer rates, as compared to electrical double layer capacitors (EDLCs). This limitation is rooted in the assumption that the kinetics of redox processes are slower than double layer processes in ECs, but is in fact due to the low conductivity of oxides and polymers used in pseudocapacitors. The high electronic conductivity of electrode material is one of the key parameters for high charge transfer rates besides the ionic conductivity and interfacial impedance.

Recently, solution processable 2D transition metal carbides (MXenes) have shown great promise as high rate pseudocapacitive materials for energy storage applications. Such kind of performance is due to their unique combination of 2D morphology, creating ionic channels between the layers, metallic conductivity (8000–10 000 S cm\(^{-1}\)), and fast surface redox reactions. For instance, titanium carbide (Ti\(_3\)C\(_2\)Tx, Tx is = O, -OH, and –F) MXene showed a specific volumetric capacitance up to 1500 F cm\(^{-3}\) along with ultra-high rate capability in three-electrode configuration. Extreme rate performance was recently reported for MXene-PEDOT composites in a sandwich device configuration.

In this study, we demonstrate that by controlling the lateral flake size and device design of MXene MSCs with interdigitated electrodes, it is possible to achieve excellent frequency response matching that of the electrolytic capacitors. Furthermore, we have been able to scale our fabrication process to the wafer scale, which proves the viability of our approach. To test the feasibility of our device, we demonstrate efficient and reliable filtering of voltage ripples using our MXene microsupercapacitors.

2. Result and Discussion

The Ti\(_3\)C\(_2\)Tx MXene was synthesized by following the minimally intensive layer delamination (MILD) method. This protocol offers not only selective etching of Al from Ti\(_3\)AlC\(_2\) MAX phase but also subsequent delamination of multilayer MXene stacks via manual shaking (see the Experimental Section). The aqueous Li ions present in the synthesis reaction are spontaneously intercalated due to negative surface charges on MXenes, facilitating delamination via simple agitation. It was reported that the MILD method produces higher quality Ti\(_3\)C\(_2\)Tx MXene flakes compared to other existing etching and delamination protocols. As synthesized Ti\(_3\)C\(_2\)Tx colloidal dispersions exhibit a Tyndall scattering effect, which is a manifestation of the inherent colloidal stability resulting from negative surface charges (Figure S1, Supporting Information). The delaminated Ti\(_3\)C\(_2\)Tx dispersions from this method have an average flake size above 1 µm which can be reduced below 0.5 µm by probe sonication (Figure 1a,b). Figure 1c shows the resulting transmission electron microscopy (TEM) images and flake size distributions obtained by scanning electron microscope (SEM). The data shows that the flake size of Ti\(_3\)C\(_2\)Tx after sonication ranges from 100 to 600 nm, with an average size of 300 nm (referred to as Ti\(_3\)C\(_2\)Tx-0.3 µm). In comparison, the flake size of Ti\(_3\)C\(_2\)Tx before sonication ranges from 1 to 4 µm, with an average size of 1.7 µm (referred to as Ti\(_3\)C\(_2\)Tx-1.7 µm) (Figure 1d).

The size distribution of Ti\(_3\)C\(_2\)Tx flakes was also estimated using dynamic light scattering (DLS), which matches quite well with the SEM images (Figure 1e), similar to previous studies on Ti\(_3\)C\(_2\)Tx. The surface functional groups of MXene endow it with a hydrophilic surface, which enables solution processing of MXenes to obtain thin films by a variety of techniques including vacuum assisted filtration, spray, spin, and dip coating with no surfactants. Four-point probe conductivity measurements showed that restacked Ti\(_3\)C\(_2\)Tx-0.3 µm films (spray-coated) exhibit an electrical conductivity up to 900 S cm\(^{-1}\) compared to 4500 S cm\(^{-1}\) for Ti\(_3\)C\(_2\)Tx-1.7 µm films. The low electrical conductivity of Ti\(_3\)C\(_2\)Tx-0.3 µm arises from the pronounced contact resistance between the small flakes (Figure 1f and Figure S2a, Supporting Information).

The X-ray diffraction (XRD) patterns of spray-coated Ti\(_3\)C\(_2\)Tx films on glass showed (002) peaks centered at 6.9°, confirming the restacking of Ti\(_3\)C\(_2\)Tx layers with similar interlayer spacing (Figure 1g). Compared with Ti\(_3\)C\(_2\)Tx-0.3 µm, Ti\(_3\)C\(_2\)Tx-1.7 µm film showed sharp (000) peaks, probably due to greater stacking in the case of large flakes. Moreover, based on Scherrer equation, the broader full width at half maximum (FWHM) of Ti\(_3\)C\(_2\)Tx-0.3 µm compared to Ti\(_3\)C\(_2\)Tx-1.7 µm also indicates random stacking of smaller flakes along the c-axis.

As illustrated in Figure 2a, MXene microsupercapacitor devices were fabricated using a photolithographic lift-off process followed by spray-coating of MXene dispersions. To form the predefined photoresist patterns, a 4 µm thick photoresist was coated onto SiO\(_2\)/Si substrate and then was exposed to ultraviolet (UV) light through a photomask. After developing in a developer solution, the exposed regions of photoresist were dissolved, leaving behind the interdigitated photoresist pattern (step 3, Figure 2a). A thin layer of Au (100 nm)/Ti (10 nm) was sputtered over the substrate as the current collector followed by O\(_2\) plasma treatment to make the gold surface hydrophilic to ensure that MXene flakes are attached firmly and uniformly (Figure S3, Supporting Information). A thin layer of Ti\(_3\)C\(_2\)Tx film was then coated onto the entire surface by spraying the water dispersion (1 mg mL\(^{-1}\)) with instantaneous drying achieved by blowing hot air (50 °C) onto the substrate. The Ti\(_3\)C\(_2\)Tx and Au/Ti metal layer deposited onto the unexposed photoresist regions were removed through an acetone lift-off process (step 6, Figure 2a). Due to the strong adhesion between the metal surface and Ti\(_3\)C\(_2\)Tx sheets, peeling of the active material was not observed even after bath sonication used for the lift-off process. The surface texture and cross-section SEM images of spray-coated Ti\(_3\)C\(_2\)Tx thin films are shown in Figure 2b,c.

The frequency response of MXene microsupercapacitors was investigated by electrochemical impedance spectroscopy
in polyvinyl alcohol/phosphoric acid (PVA/H₃PO₄) gel electrolyte. The typical charge storage mechanism of Ti₃C₂Tx in acid medium is explained as follows:[41]

\[
\text{Ti}_3\text{C}_2\text{O}_x(\text{OH})_y\text{F}_z + e^- + H^+ \leftrightarrow \text{Ti}_3\text{C}_2\text{O}_{x-y}(\text{OH})_{y-a}\text{F}_z
\]  

(1)

The impedance phase angles of the devices with the same width and interspacings of 100 µm (shown in the inset of Figure 2d) are plotted versus frequency and compared with a commercial aluminum electrolytic capacitor in Figure 2d. For AC-line filtering applications, the phase angle should be near −90° at 120 Hz.[1] Previous density functional theory (DFT) calculations have shown that smaller Ti₃C₂Tx flakes with more edge planes have stronger adsorption of N₂, indicating that there is possibly a relationship between flake size and electrochemical reactivity.[42] Not surprisingly, as can be seen in Figure 2d, our optimized Ti₃C₂Tx-0.3 µm microsupercapacitor exhibits phase angles of −76° at 120 Hz, close to commercial AEC (phase angle of −84° at 120 Hz). In contrast, the Ti₃C₂Tx-1.7 µm microsupercapacitor exhibited a phase angle of −60° at 120 Hz. The cross-over frequency at which the impedance phase angle reaches −45° is also an important parameter to study. The typical cross-over frequencies (f) of Ti₃C₂Tx-1.7 µm and Ti₃C₂Tx-0.3 µm MSCs are found to be 220 and 1100 Hz, respectively.

Amazingly, although Ti₃C₂Tx-0.3 µm has lower electrical conductivity compared to Ti₃C₂Tx-1.7 µm, its equivalent series resistance (ESR) value is slightly lower (ESR, 0.2 Ω cm²) than that of Ti₃C₂Tx-1.7 µm (ESR, 0.5 Ω cm²) (Figure 2e). This indicates that ion transport and accessibility are equally important besides the electronic conductivity of the films. In this case, a typical electronic conductivity of a few hundred S cm⁻¹ is enough for high rate charge/discharge provided that the films have sufficient ionic conductivity.[1] There are no semicircles observed in the high frequency region for both cases, indicating that negligible interfacial impedance issues. We expect that the oxygen plasma treatment of Au surface results in strong adhesion of MXene flakes, giving rise to near ohmic contacts. Furthermore, our results show that the Ti₃C₂Tx-0.3 µm film has a more capacitive nature toward lower frequencies compared to Ti₃C₂Tx-1.7 µm, as a more vertical line is observed. This can be explained by the relatively shorter ion transport path and lesser face to face restacking of the sheets for Ti₃C₂Tx-0.3 µm films compared to Ti₃C₂Tx-1.7 µm, as shown in inset of Figure 2e.
Cyclic voltammograms (CVs) of a Ti₃C₂Tx-0.3 µm MSC exhibit rectangular behavior with high rate capability (Figure 3a). These CVs retain quasi-rectangular shapes even at a high scan rate of 300 V s⁻¹ (Figure 3b). The ultra-high scan rate capability can be attributed to accessibility of the entire volume of the thin film to the electrolyte ions with little diffusion limitations. For an ideal capacitor, which has constant capacitance, the current response should be linearly proportional to the scan rate based on the definition of capacitance ($C = I / \text{scan rate}$). The current response of our devices exhibits linear dependence on scan rates up to 300 V s⁻¹ (Figure 3c), which is the highest rate among all reported MXene microsupercapacitors (Figure 3d).[37,40,43] In contrast, CVs of the large-flake Ti₃C₂Tx can retain a rectangular shape at a maximum scan rate of 30 V s⁻¹ (the pure MXene...
film without gold has a maximum scan rate of 3 V s$^{-1}$, Figure S4a, Supporting Information). Though Ti$_3$C$_2$Tx thin films exhibit broad redox peaks in the three-electrode configuration (Figure S5, Supporting Information), the device showed quite rectangular CVs. This indicates that MXene electrodes exhibit typical capacitive behavior with superior electronic conductivity compared with other solution processable nanomaterials.

However, at a scan rate of 1 V s$^{-1}$, both Ti$_3$C$_2$Tx-0.3 and Ti$_3$C$_2$Tx-1.7 µm showed similar areal capacitance of about 0.5 mF cm$^{-2}$ (Figure S4b, Supporting Information), suggesting that the flake size may not play a critical role in the maximum possible capacitance at low scan rates, since ions have enough time to access the entire volume of the film. The galvanostatic charge/discharge curves in Figure 3e show symmetric triangular-shaped curves. The Ohmic drop is small even at a high current density of 60 A cm$^{-2}$, which is a result of the good conductivity of Ti$_3$C$_2$Tx electrodes. Figure 3f displays the real ($C'$) and imaginary ($C''$) capacitances of the Ti$_3$C$_2$Tx-0.3 µm microsupercapacitor, which were extracted from the EIS spectra. The characteristic relaxation time constant ($\tau_0$) can be obtained from the frequency ($f_0$) at which imaginary capacitance $C''$ reaches the maximum value.\(^{[45]}\) It is the time required for discharging a capacitor with an energy efficiency greater than 50%. Capacitive behavior dominates at frequencies below $\tau_0$ and resistive behavior at frequencies above $\tau_0$. The characteristic relaxation time constant ($\tau_0 = 1/f_0$) was estimated to be 1 ms, which is much better than the typical activated carbon EDLCs (usually a characteristic response time of \approx 1 s).\(^{[46]}\) Capacitance at 120 Hz is estimated to be \approx 300 µF cm$^{-2}$ from real capacitance $C'$, at an impedance of 2 Ω cm$^2$, yielding a resistor-capacitor (RC) time constant (reflecting how fast the capacitor can be charged/discharged) of 0.6 ms. Such kind of RC time constant of capacitors is sufficient for 120 Hz filtering applications (8.3 ms). The corresponding volumetric capacitance is calculated to be 30 F cm$^{-3}$. For full-wave rectifier line filtering applications, the ripple ($r$) in the final output is approximated as

$$r = \frac{1}{2fR}$$(2)

where $f$ is frequency and $R$ is load resistance.\(^{[47]}\) The amount of capacitance is critical for a given level of ripples, while the
voltage window of the capacitor restricts the maximum input voltage. Thus, large capacitances and high working voltages are two key parameters for optimizing performance, which can be given by the charge \( Q = CV \) of the device. The MXene microsupercapacitors stored a charge of 18 FV cm\(^{-3}\) (or C cm\(^{-3}\)) compared to 0.14 FV cm\(^{-3}\) for a low-voltage Al-electrolytic capacitor (KDK, Tokyo, Japan), showing that MXene MSCs can have comparable rate capability while occupying a much smaller volume. Figure 3g shows 100 integrated MSCs fabricated on a 4 in. SiO\(_2\)/Si wafer, a great advancement compared to other reports, which lack compact integration and high voltage window operation for real applications. Wafer-scale fabrication of microsupercapacitors with single and series-connected microsupercapacitors is very important for device applications.[11,48] The CVs of 10 cells connected in series show nearly rectangular shape up to a scan rate of 300 V s\(^{-1}\) with 6 V voltage window (Figure 3h). The galvanostatic charge-discharge profiles exhibited symmetric triangular shapes, with little voltage drop, and with excellent coulombic efficiency (Figure 3i). Besides silicon substrates, we have also fabricated large scale MSCs on flexible polyethylene terephthalate (PET) substrate, which can be useful for wearable electronics and sensing applications (Figure S6, Supporting Information).

Besides flake size, the frequency response of MSCs can be controlled by the thickness of the electrodes and spacing of the fingers. When thickness was increased from 100 to 200 nm, a decrease in frequency response measured at ~45° was observed (Figure 4a). In contrast, when the thickness of the Ti\(_3\)C\(_2\)T\(_x\)-0.3 µm decreased from 100 to 20 nm, the phase angle at 120 Hz improved from ~76° to ~82°, while the cross-over frequency at ~45° increased from 1100 to 11 000 Hz. Such a high cross-over frequency at a phase angle of ~5° is superior to the reported electrochemical capacitors[49–58] with different geometry configurations, as shown in Table S1 (Supporting Information). This significantly improved electrochemical performance due to the decreased transport distance of the ions as confirmed by the Nyquist plot (Figure S7a, Supporting Information). However, areal capacitance decreased from 0.5 to 0.1 mF cm\(^{-2}\) when the thickness decreased from 100 to 20 nm (Figure S7b, Supporting Information). The trade-off between areal capacitance and frequency response is due to the electrode mass loading and ion accessibility. To confirm the influence of the ion transport path length, we have further fabricated Ti\(_3\)C\(_2\)T\(_x\) microsupercapacitors with the same finger width (100 µm) and thickness (100 nm) but different inter-finger spacings, as shown in Figure 4b. It is evident that devices with smaller inter-finger spacings show faster response time, in agreement with previous studies.[22] The cross-over frequencies of the devices (optical images for different electrode spacings of 100, 50, 25, and 10 µm are shown in Figure S8, Supporting Information) at ~45° were found to be 1100, 1400, 1900, and 2600 Hz, respectively. When interfinger
spacing decreases, ions have shorter pathways to travel between the electrodes. As a result, the relaxation time constant of the device with 10 µm spacing decreases to 0.45 ms (Figure S9, Supporting Information). A summary of the performance of the MXene MSCs fabricated in this study is shown in Table S2 in the Supporting Information.

To demonstrate the AC-line filtering with MXene MSCs, a filter circuit was constructed as shown in Figure 4c. The 60 Hz sinusoidal AC input signal is first generated by a full-wave function generator with 50 Ω internal load resistance (filtering efficacy of a variety of capacitors fabricated in this study are under the same load) and then converted to a 120 Hz DC signal via a full-wave bridge rectifier (Figure S10, Supporting Information). After passing the rectified signal through the MXene microsupercapacitor, a substantially smoothed output signal is obtained (Figure 4d). As shown in Figure 4d, the AC signal with a peak voltage of 0.6 V was successfully converted and smoothed to a constant output positive voltage (+0.56 V) using both our microsupercapacitor and a commercial 4 mF electrolytic capacitor. The successful conversion of the AC signal to constant voltage was enabled by the high volumetric capacitance and fast response of our Ti₃C₂Tx microsupercapacitor. For comparison, we have also tested commercial AECs (with smaller capacitance than our device) and commercial activated carbon supercapacitors (phase angle of 0° at 120 Hz) and showed that MXene outperformed the commercial devices. Specifically, the former shows output voltage with spikes (Figure S11, Supporting Information) and the latter shows a 0 V output (Figure S12, Supporting Information). Furthermore, the AC-filtering function of the Ti₃C₂Tx microsupercapacitor was demonstrated up to high frequencies of 600 and 1500 Hz (Figure S13, Supporting Information). In addition, cycling test of a single-cell microsupercapacitor showed almost no voltage drop even after 1 week of continuous operation (more than 7 × 10⁷ cycles) using 60 Hz AC input sinusoidal signals (Figure S14, Supporting Information).

While this study indicates robust operation of MXene microsupercapacitors for AC-line filtering applications, it is important to note that we expect further improvement by selecting other MXenes from more than 30 available compositions and optimizing the device design, such as further decrease in flake size and spacing/geometry of finger electrodes.

3. Conclusion

In summary, we have developed electrochemical microsupercapacitors for AC-line filtering applications using solution processable 2D MXene (titanium carbide) nanosheets. Our results show that the frequency response of the MXene MSCs are highly dependent on flake size, thickness of the electrodes, and spacing between the electrode fingers. Specifically, devices with 100 nm thick electrodes and 10 µm spacing delivered a volumetric capacitance of 30 F cm⁻³ at 120 Hz, performed well at 300 V s⁻¹, and had a relaxation time constant of τ₀ = 0.45 ms, outperforming electrolytic capacitors (τ₀ = 0.8 ms). The optimized MXene microsupercapacitors were produced at the wafer scale and could filter out pulsed DC voltage ripples. Given the good performance characteristics and scalability, it can be concluded that MXene microsupercapacitors represent a viable alternative to bulky electrolytic capacitors for filtering and other applications.

4. Experimental Section

Synthesis of Delaminated Ti₃C₂Tx MXene with Different Flake Sizes: All chemicals were used as received without further purification. Ternary carbide, Ti₃AlC₂ (MAX phase) powder was commercially procured from Carbon-Ukraine Ltd, particle size <40 µm. Ti₃C₂Tx MXene was synthesized via minimally intensive layer delamination method, in which selective extraction of aluminum from Ti₃AlC₂ was done through in situ HF-forming etchant as previously reported. The etching solution was prepared by adding 1 g lithium fluoride (LiF, Alfa Aesar, 98+%) to 20 mL of 9 m hydrochloric acid (HCl, Fisher, technical grade, 35–38%), followed by stirring for 5 min. 1 g of Ti₃AlC₂ powder was slowly added to the MILD etchant at 35 °C and stirred for 24 h. The acidic suspension was washed with deionized (DI) water until pH ≥ 6 via centrifugation at 3500 rpm (5 min per cycle) and decanting the supernatant after each cycle. Around pH ≥ 6, stable dark green supernatant of Ti₃C₂Tx was observed and then collected after 5 min of centrifugation at 3500 rpm. As prepared Ti₃C₂Tx suspension has an average flake size above 1 µm. To obtain Ti₃C₂Tx with smaller flake sizes, Ti₃C₂Tx suspension was sonicated for 45 min by using a tip sonicator (Sonics, vibracell) with a 5 s ON pulse and a 5 s “OFF” pulse at an amplitude of 40% under stirring in an ice bath. After sonication, no sediment is observed and the suspension was centrifuged at 3500 rpm for 10 min. The concentration of Ti₃C₂Tx solution was measured by filtering specific amounts of colloidal solution through a polypropylene filter (3501 Coated PP, Celgard LLC, Charlotte, NC), followed by drying under vacuum at 70 °C overnight.

Preparation of MXene Microelectrodes: SiO₂/Sl substrates (Fisher Scientific) were cleaned by sequential bath sonication in acetone, isopropanol, and deionized water for 5 min each. Positive photoresist ECI AZ3027 was spun at 3000 rpm for 30 s to achieve ~4 µm photoresist layer followed by soft baking at 100 °C for 60 s. Photoresist layer was exposed through EVG contact aligner at a constant dose of 210 mJ cm⁻² through the Cr/glass mask with the predesigned patterns. Interdigitated fingers have a typical width of 100 µm and length of 2000 µm, while varied interspacings of 25–100 µm. After exposure, samples were developed in AZ726 developer for 60 s, followed by rinsing immediately in deionized water. Samples were then dried and 100 nm Au/10 nm Ti was deposited by reactive ion sputtering (Equipment Support Co., Cambridge, England) with 400 W at 5 mTorr pressure.

Prior to spray-coating of MXene, gold-coated substrates were treated with O₂ plasma (Plasmaflo PDC-FMG, USA) for 5 min per cycle) and decanting the supernatant after each cycle. Around pH ≥ 6, stable dark green supernatant of Ti₃C₂Tx was observed and then collected after 5 min of centrifugation at 3500 rpm. As prepared Ti₃C₂Tx suspension has an average flake size above 1 µm. To obtain Ti₃C₂Tx with smaller flake sizes, Ti₃C₂Tx suspension was sonicated for 45 min by using a tip sonicator (Sonics, vibracell) with a 5 s ON pulse and a 5 s “OFF” pulse at an amplitude of 40% under stirring in an ice bath. After sonication, no sediment is observed and the suspension was centrifuged at 3500 rpm for 10 min. The concentration of Ti₃C₂Tx solution was measured by filtering specific amounts of colloidal solution through a polypropylene filter (3501 Coated PP, Celgard LLC, Charlotte, NC), followed by drying under vacuum at 70 °C overnight.
Material Characterization: X-ray diffraction patterns were collected by a Bruker diffractometer (D8 Advance) with Cu Kα radiation, λ = 1.5406 Å. The morphology and microstructure of the samples were characterized by a scanning electron microscope (Nova Nano 630, FEI).

\[ \tau = \frac{1}{f} \int |z|^2 \, dv \]  

where \( i \) is the discharge current (mA), \( V \) is the potential window (V), \( v \) is the scan rate (V s\(^{-1}\)), and \( A \) is the area of the electrode (cm\(^2\)).

2-Electrode Configuration (Device Measurements): Areal capacitance (mF cm\(^{-2}\)) of the devices was calculated from the CV curves by integrating the discharge portion using the following equation

\[ C = \frac{1}{2 \pi V} \int dV \]  

where \( i \) is the discharge current (mA), \( V \) is the voltage window (V), \( v \) is the scan rate (V s\(^{-1}\)), and \( A \) is the total area of fingers covered with the electrolyte. To calculate volumetric capacitance, areal capacitance was divided by thickness (cm) of the active materials.

Impedance Spectra: The real (\( C' \)) and imaginary (\( C'' \)) parts of capacitances were calculated using the following equations

\[ C' = \frac{-Z''}{(2 \pi f A |Z|^2)} \]  

\[ C'' = \frac{Z'}{(2 \pi f A |Z|^2)} \]  

where \( |Z| \) is the absolute value of impedance (\( \Omega \)), \( Z' \) and \( Z'' \) are the real and imaginary components of impedance, \( f \) is the frequency (Hz), and \( A \) is the geometrical area of the devices.

RC time constants (\( \tau_{RC} \)) at each frequency were calculated using the formula

\[ \tau_{RC} = \frac{Z''}{C'} \]
